

## **Reproduction and Development\_Animal\_Mechanisims of Sexual Reproduction\_SLFAB2**

### **MECHANISMS OF SEXUAL REPRODUCTION**

During external fertilization, both eggs and sperms are shed from the body and random fertilization occurs in an aquatic medium. Further protection is made possible by the gelatinous coat in eggs. To ensure that a zygote or zygotes are formed, release of thousands of sperms and eggs are an ideal situation. Evolution tells that from fish-like ancestors, amphibians evolved by invading the land to find more food sources. Gradually, amphibians evolved into reptiles and eventually to mammals. The change in environment necessitated a modification of sexual strategies such that internal fertilization was invented. Sperms still fertilize the egg in the aquatic environment provided by the female reproductive track. The amniote egg was a necessary step as a protection and to maintain the egg and the zygote later in a moist environment.

Internal fertilization requires cooperation thus, courtship is only a stepping stone towards this process. More complicated reproductive systems including copulatory organs have to be developed to ensure that the sperm is placed near or at the vicinity of the female reproductive tract. To ensure the embryo resistant eggshells and development inside

reproductive tract have been developed. Even after born, parental care of the egg and nourishment became a necessary step towards the survival of the

Kangaroos and opossums are marsupials that embryos for a short time in the uterus. Afterward crawls out and completes their fetal development in a mammary gland. In eutherian mammals, development inside the uterus, nourished by the mother's blood placenta. The baby is born and further care and given to the offspring sometimes up to maturity. In cases of parental care in the animal kingdom all selective advantage for the perpetuation of organisms

## **GAMETOGENESIS**

The organs that produce gametes in most animals are called gonads. This is the minimum reproductive system and more complicated ones involve accessory tubes and glands that protect and carry developing sex cells and embryos. Polychaete worms (Phylum Annelida) have separate sexes. The eggs and sperms develop from cells lining the coelom. As gametes mature, they are extruded from the body wall and fill the coelom. Gametes may be shed through excretory openings. In some cases the swelling mass of eggs split the body open and the parent is killed. In a certain type of wasp, the eggs are deposited in a caterpillar.

Here the embryos emerge and they consume the caterpillar as food from the inside out.

## SPERMATOGENESIS

Spermatogenesis is the process of sperm cell production in the primary sex organ of males, the testis (Figure 4.7). Inside a testis, there are many coiled seminiferous tubules. These tubules end up in the epididymis which is attached on top of the testis.

is.

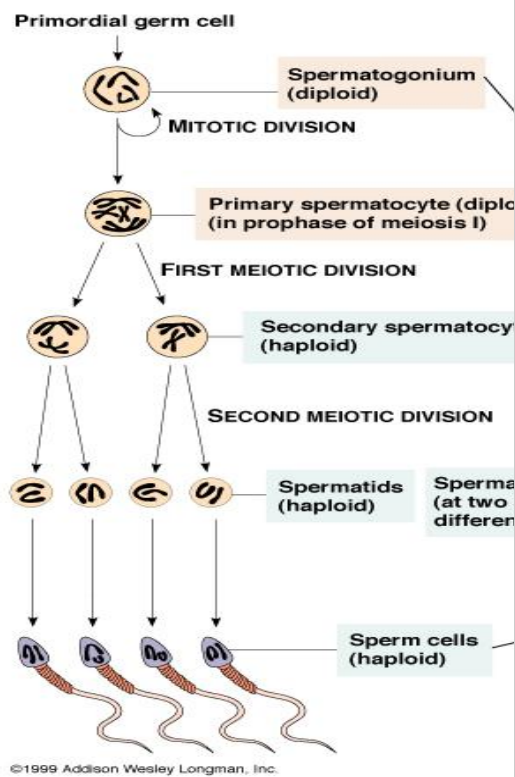

Figure 4.7 Spermatogenesis

In one seminiferous tubule, primordial germ cells in the embryo divide into numerous spermatogonia, which are diploid cells which will later exhibit meiosis. Development of these cells is stimulated from the hypothalamus trigger the release of gonadotropin-releasing hormone (GnRH) which stimulates the anterior pituitary to release FSH (follicle stimulating hormone) and LH (luteinizing hormone). The FSH then travels through the bloodstream and acts on the testis to stimulate spermatogenesis. GnRH also triggers the release of LH (luteinizing hormone) from the anterior pituitary to produce androgen and other male sex hormones such as testosterone. Androgens are steroid hormones produced in the cells of the testis. Primary and secondary sex characteristics are then developed in the male. Examples of the latter are development of stronger muscles, body and facial hair, deepening of the voice and narrowing of the hips, all associated with maleness.

## **OOGENESIS**

Oogenesis is the process where ova are developed in the primary sex organ of females, the ovary (Figure 4.9). When a human baby girl is born, all the potential egg cells that will later mature are already contained in the miniature ovary.

Unlike spermatogenesis, oogenesis is characterized by gap periods and sex cells are triggered by puberty and subsequent release of female hormones similar to the one described for spermatogenesis.

the

In ovary,

primordial germ cells develop into a primary oocyte with several follicles but onset of puberty. The primary oocyte produces a haploid secondary oocyte. Most of the cytoplasm is in the secondary oocyte. At ovulation, the follicle releases the secondary oocyte away from the ovary. If a sperm is available, fertilization may occur and the secondary oocyte develops by Meiosis II

Each oogonium grows into a primary oocyte. FSH triggers the growth of several follicles but only one follicle matures every month at the onset of puberty. The primary oocyte undergoes Meiosis I to produce a haploid secondary oocyte and a very small polar body. Most of the cytoplasm is in the secondary oocyte. During ovulation, the follicle releases the secondary oocyte away from the ovary. If a sperm is available, fertilization may occur and the secondary oocyte develops by Meiosis II

into an ootid and finally to a mature ovum, with the subsequent release of a second polar body. For every primary oocyte which undergoes Meiosis, there is only one functional product, the ovum. The polar bodies are not fertilized.

Estrogen is the most common female hormone. It is responsible for triggering secondary female sex characteristics such as development of the breasts, change in voice quality and widening of the pelvic girdle, all in preparation for pregnancy and motherhood. During the first time that the human female ovulates but there is no fertilization, the follicular tissue (which contained the secondary oocyte) develops into a corpus luteum which disintegrates. If the female is fertilized, the corpus luteum helps sustain pregnancy by secreting progesterone.
